Abstract

With the advent of Deep Learning models, it was only natural that new methods for handling missing data were developed using deep learning models. These methods use Stochastic Gradient Descent (SGD) to optimize their parameters. The performance SGD relies on the sampling of a mini-batch from the distribution which is notoriously inefficient. In this paper, we try to leverage the extra information in the mask to allow for an informed sampling of the dataset. This informed sampling allows us to reduce the variance from the estimation of the gradient.

1. Introduction

Missing data is omnipresent in the real world and is an obstacle in many data analysis problems. Indeed, due to its semi-discrete nature with the mix between continuous (observed data) and categorical (missing data), it is difficult to apply the traditional machine learning method to this data directly. Nonetheless, many recent papers use deep learning models that allow for scalable imputation of the missing values (Ipsen et al., 2020; Mattei & Frellsen, 2019; Kyono et al., 2021) or prediction using a dataset with missing values (Le Morvan et al., 2020; Ipsen et al., 2022).

Such models are trained with **Stochastic Gradient Descent** (SGD) (Kiefer & Wolfowitz, 1952). This requires sampling a subset of data points to obtain an estimate of gradient and taking a step of this gradient estimation. SGD is notoriously inefficient in its vanilla version.

Different improvements were proposed for SGD. Either some variations on how to handle the estimation of the gradients or by improving the sampling to sampled more informative points using importance sampling.

Preliminary work. Under review by the International Conference on Machine Learning (ICML). Do not distribute.

In this paper, we propose leveraging the extra information given by the mask to accelerate the training of different problems with missing data.

2. Related Work

Stochastic Gradient Descent (SGD) and its variants form the backbone of modern deep learning optimization. Improvements to SGD can be broadly categorized into two approaches: (1) adaptive gradient methods that modify the update rule, and (2) variance reduction techniques that improve mini-batch sampling.

2.1. Adaptive Gradient Methods

A rich line of work focuses on modifying the SGD update rule to accelerate convergence. **Momentum-based methods** (Polyak, 1964; Sutskever et al., 2013) accumulate exponentially decaying moving averages of past gradients to dampen oscillations and accelerate convergence in relevant directions. **Nesterov accelerated gradient** (Nesterov, 1983) achieves provably faster convergence rates for convex objectives by computing gradients at a "lookahead" position.

Adaptive learning rate methods adjust step sizes per parameter based on gradient history. **AdaGrad** (Duchi et al., 2011) scales learning rates inversely to the square root of accumulated squared gradients, enabling larger updates for infrequent features. **RMSProp** (Tieleman & Hinton, 2012) addresses AdaGrad's aggressive learning rate decay by using an exponentially decaying average. **Adam** (Kingma & Ba, 2014) combines momentum with adaptive learning rates, maintaining both first-moment (momentum) and second-moment (variance) estimates of gradients. **AdamW** (Loshchilov & Hutter, 2019) improves Adam by decoupling weight decay from gradient-based updates.

Beyond diagonal preconditioning, **natural gradient methods** (Amari, 1998) use the Fisher information matrix to define a metric that is invariant to model parameterization, though exact computation is often prohibitive. Practical approximations include **K-FAC** (Martens & Grosse, 2015) which approximates the Fisher matrix using Kronecker-factored structures.

2.2. Variance Reduction Methods

An orthogonal approach reduces the variance of gradient estimates through improved sampling or gradient estimation.

Variance-reduced gradient estimators maintain auxiliary information to reduce noise. **SVRG** (Johnson & Zhang, 2013) periodically computes full gradients and uses them to correct stochastic gradient estimates, achieving linear convergence for strongly convex objectives. **SAGA** (Defazio et al., 2014) maintains a table of individual gradient estimates and updates them incrementally, achieving similar convergence guarantees without periodic full gradient computations. **SAG** (Schmidt et al., 2017) uses an averaged gradient from stored per-example gradients.

Importance sampling (Zhao & Zhang, 2015) assigns non-uniform sampling probabilities to training examples based on their contribution to variance. Ideally, examples are sampled proportionally to their gradient norms, but this requires expensive per-example gradient computation. (Katharopoulos & Fleuret, 2018) circumvent this by deriving upper bounds on gradient norms using only forward passes, enabling prioritized sampling with reduced computational overhead. (Johnson & Guestrin, 2018) propose adaptive importance sampling where sampling distributions are updated based on observed gradient statistics.

2.3. Stratified Sampling

Stratified sampling (Owen, 2013), a classical variance reduction technique from survey statistics, partitions the dataset into homogeneous strata and samples from each stratum proportionally to its importance. Unlike importance sampling, stratification guarantees coverage of all strata and is more robust to distribution shift.

(Zhao & Zhang, 2014) apply stratified sampling to SGD by clustering input features using k-means under the assumption that gradients are Lipschitz-continuous with respect to inputs. (Gopal, 2016) propose using side information (e.g., class labels) to define strata, demonstrating improved convergence on classification tasks. (Zhang et al., 2017) introduce **determinantal point processes** (DPPs) as a continuous relaxation of stratified sampling, constructing mini-batches with diverse examples via a learned similarity kernel. (Zhang et al., 2019) extend this to adaptive point processes where repulsivity is lower near decision boundaries to focus sampling on hard examples.

(Lu et al., 2021) provide theoretical analysis showing that stratified sampling with optimal Neyman allocation (Neyman, 1934) provably reduces SGD variance and iteration complexity. However, prior work has not leveraged the natural stratification provided by missing data patterns.

2.4. Our Contribution

We propose leveraging the missing data mask as a natural, zero-cost stratification variable. Unlike prior methods that require clustering (Zhao & Zhang, 2014), label information (Gopal, 2016), or learned kernels (Zhang et al., 2017), the mask S is already available and induces heterogeneous gradient distributions under MCAR. We derive closed-form expressions for optimal strata boundaries using the Dalenius-Hodges criterion (Dalenius & Hodges Jr, 1959) and prove that count-based stratification achieves $O(1/d)$ regret with a matching lower bound. Our approach combines theoretical optimality with practical simplicity.

3. Batch Sampling

3.1. Stochastic Gradient Descent

We have a process that is modelled by the true distribution $p_{X,Y}$. A missing process obscures parts of X resulting in the mask random variable S following a missing process $p(S|X,Y)$. We have a function, usually a neural network f_θ parameterizing some distribution. We consider the following quantity that we want to optimize according to θ.

$$\mathbb{E}_{X,Y,S}[\mathcal{L}(f(X,S;\theta),Y)] \tag{1}$$

Usually, we just have access to N realizations $(x_i, s_i, y_i)_{i\in[0,N]}$ of this process, hence the minimization of the empirical risk.

$$\theta^* = \underset{\theta}{\operatorname{argmin}} \frac{1}{N}\sum_{i=1}^{N} \mathcal{L}\left(f\left(x_i, s_i; \theta\right), y_i\right) \tag{2}$$

We use an SGD procedure with learning rate η, where the update at iteration t depends on the sampling distribution P and re-scaling coefficients $w_1^t, \ldots, w_N^t$. Let I_t be a subset of data points sampling such that $|I_t| = b \in \mathcal{N}$. We consider the following update rule :

$$\theta_{t+1} = \theta_t - \eta \frac{1}{B}\sum_{i\in I_t} w_{i,t} \nabla_{\theta_t} \mathcal{L}\left(f\left(x_{i,t}, s_{i,t}; \theta_t\right), y_{i,t}\right) \tag{3}$$

which can be written more compactly as:

$$\theta_{t+1} = \theta_t - \eta G_{I_t} \tag{4}$$

where $G_{I_t} = \frac{1}{B}\sum_{i\in I_t} w_{i,t} \nabla_{\theta_t} \mathcal{L}\left(f\left(x_{i,t}, s_{i,t}; \theta_t\right), y_{i,t}\right)$

We want to get an unbiased estimator G_i such that $\mathbb{E}_{P_t}[G_{I_t}] = \nabla_\theta \mathbb{E}_{X,Y,S}[\mathcal{L}(f(X,S;\theta),Y)]$. The traditional method corresponds to sample uniformly from the dataset, meaning $w_{i,t} = 1$ and $P_t(i \in I_t) = \frac{b}{N}$.

Following derivation from (Katharopoulos & Fleuret, 2018), we have an estimate of $S = -\mathbb{E}_{P_t}\left[\|\theta_{t+1}-\theta^*\|_2^2 - \|\theta_t-\theta^*\|_2^2\right]$ the speed of convergence :

$$S = 2\eta\,(\theta_t-\theta^*)\,\mathbb{E}_{P_t}\left[G_{I_t}\right] - \eta^2\mathbb{E}_{P_t}\left[G_{I_t}\right]^T\mathbb{E}_{P_t}\left[G_{I_t}\right] - \eta^2\,\mathrm{Tr}\left(\mathbb{V}_{P_t}\left[G_{I_t}\right]\right) \tag{5}$$

Having an unbiased gradient estimator with less variance allows for a speed up of the training process.

For simplicity, for the rest of the calculation, we consider that we sample a single example per batch (ie $b = 1$) and we note $\nabla_{i,\theta} = \nabla_\theta \mathcal{L}(f(x_i, s_i; \theta), y_i)$

3.2. Stratified Sampling

Following (Owen, 2013), we can reduce the variance of a Monte-Carlo estimator using stratified sampling. Instead of sampling uniformly from the dataset, we partition the data into K mutually exclusive strata $R_1, \dots, R_K$ with $\bigcup_{k=1}^K R_k = \{1, \dots, N\}$.

3.2.1. Sampling scheme and gradient estimator

We sample a stratum k with probability p_k (where $\sum_{k=1}^K p_k = 1$), then uniformly sample one example from that stratum. To maintain an unbiased gradient estimate, we reweight each sample by the inverse of its sampling probability. This gives the gradient estimator:

$$G_{i_t} = \nabla_{i_t,\theta} \cdot \frac{|R_k|}{N p_k} \quad \text{where } i_t \in R_k \tag{6}$$

This estimator is unbiased: $\mathbb{E}_{i\sim P_s}[G_i] = \mathbb{E}_{i\sim P_u}[G_i]$ (see Appendix A.1 for proof). The key insight is that while the expectation remains unchanged, we can choose p_k to minimize the variance.

3.2.2. Optimal sampling probabilities

We seek to minimize the variance of our gradient estimator $\mathrm{Tr}(\mathbb{V}_{P_s}[G_i])$. Define ssg_k as the mean squared gradient norm within stratum k:

$$ssg_k = \frac{1}{|R_k|}\sum_{i\in R_k}\|\nabla_{i,\theta}\|_2^2 \tag{7}$$

Theorem 3.1 (Optimal Stratified Sampling)**.** *The variance-minimizing sampling probabilities are:*

$$p_k^* = \frac{|R_k|\sqrt{ssg_k}}{\sum_{j=1}^K |R_j|\sqrt{ssg_j}} \tag{8}$$

The proof (Appendix A.2) follows from Lagrange optimization. Intuitively, we sample more frequently from strata with (1) more data points and (2) larger gradient magnitudes.

3.2.3. Variance reduction guarantee

Theorem 3.2 (Variance Reduction)**.** *Stratified sampling with optimal probabilities always reduces variance compared to uniform sampling:*

$$Tr(\mathbb{V}_{P_u}[G_i]) \geq Tr(\mathbb{V}_{P_s}[G_i]) \tag{9}$$

with equality if and only if ssg_k is constant across all strata.

This follows from the Cauchy-Schwarz inequality (proof in Appendix A.3). The relative improvement in variance is:

$$\frac{\mathrm{Tr}(\mathbb{V}_{P_u}[G_i]) - \mathrm{Tr}(\mathbb{V}_{P_s}[G_i])}{\mathrm{Tr}(\mathbb{V}_{P_s}[G_i])} = \sum_k \frac{N}{|R_k|}(p_k^*)^2 - 1 \tag{10}$$

This quantity is large when the ssg_k values vary substantially across strata—precisely the setting where stratification helps most.

3.3. How to find a good stratum?

The effectiveness of stratified sampling depends critically on the choice of strata. From the variance reduction formula, we see that the improvement over uniform sampling is:

$$\frac{Tr(V_{P_u}(G_i)) - Tr(V_{P_s}(G_i))}{Tr(V_{P_s}(G_i))} = \sum_k \frac{N}{|R_k|}p_k^2 - 1 \tag{11}$$

This quantity is maximized when the ssg_k values differ substantially across strata—that is, when different strata have different gradient magnitudes. Conversely, if all strata have identical ssg_k, there is no benefit from stratification.

3.3.1. Properties of good strata

From a theoretical standpoint, an ideal stratification should satisfy:

1. **Homogeneity within strata**: Points within the same stratum should have similar gradient norms, minimizing intra-stratum variance σ_k^2.
2. **Heterogeneity across strata**: Different strata should have different mean gradient norms μ_k, maximizing the benefit of non-uniform sampling.
3. **Computational efficiency**: The stratification should be cheap to compute and should not require forward/backward passes.

Previous work has used various side information for stratification: (Zhao & Zhang, 2014) used k-means clustering

on input features, while (Gopal, 2016) used class labels to define strata. However, these approaches either require expensive pre-computation or are limited to classification tasks.

3.3.2. Missing patterns as natural strata

In the context of missing data, we argue that the **missing mask s_i provides an ideal stratification variable**. Consider partitioning the dataset by unique mask patterns:

$$R_k = \{i : s_i = s^{(k)}\} \tag{12}$$

where $s^{(1)}, \ldots, s^{(K)}$ are the K unique mask patterns in the dataset.

This stratification satisfies our desiderata:

- **Homogeneity**: Points with the same mask pattern have gradients computed over the same subset of features, leading to similar gradient structures.
- **Heterogeneity**: Different mask patterns induce fundamentally different gradient computations. As we show in Section 4.1, the expected gradient norm depends strongly on which features are observed.
- **Efficiency**: The mask s_i is already available, no additional computation is required.

3.3.3. Handling many patterns

In high-dimensional settings, the number of unique mask patterns K can be large (up to 2^d for d features). We propose two strategies:

Grouping by missingness level: Define strata by the number of observed features:

$$R_k = \{i : \|s_i\|_1 = k\}, \quad k \in \{1, \ldots, d\} \tag{13}$$

This reduces K from exponential to at most d strata.

Grouping by important features: If certain features are known to be more predictive, group patterns by whether these features are observed. For instance, with a set of important features $\mathcal{I} \subset \{1, \ldots, d\}$:

$$R_k = \{i : s_i|_{\mathcal{I}} = s^{(k)}|_{\mathcal{I}}\} \tag{14}$$

3.3.4. Estimating stratum importance

The optimal sampling probabilities require knowledge of ssg_k, which depends on the current parameters θ_t. We propose an online estimation procedure:

At each epoch, maintain running estimates $\widehat{ssg}_k$ by accumulating squared gradient norms:

$$\widehat{ssg}_k^{(t+1)} = (1-\alpha)\widehat{ssg}_k^{(t)} + \alpha \cdot \|\nabla_{i,\theta_t}\|_2^2 \tag{15}$$

for each sampled point $i \in R_k$, where α is a smoothing parameter. The sampling probabilities are then updated as:

$$\hat{p}_k = \frac{|R_k|\sqrt{\widehat{ssg}_k}}{\sum_{j=1}^{K} |R_j|\sqrt{\widehat{ssg}_j}} \tag{16}$$

This adaptive scheme converges to the optimal probabilities as training progresses while adding negligible computational overhead.

4. Examples

4.1. Simple Linear Regression

We illustrate the benefit of mask-based stratification with a linear regression example. Consider data generated as:

$$Y = X^T\beta^* + \epsilon \tag{17}$$

where $X \in \mathbb{R}^d$ with $X \sim \mathcal{N}(0, \Sigma)$, $\epsilon \sim \mathcal{N}(0, \sigma_\epsilon^2)$, and $\beta^* \in \mathbb{R}^d$ is the true parameter. We observe X through a mask $S \in \{0,1\}^d$ where $S_j = 1$ indicates feature j is observed.

We handle missing data by zero-imputation: the model sees $X \circ S$ (element-wise product) and predicts $\hat{Y} = (X \circ S)^T\beta$. The squared loss for sample i is:

$$\mathcal{L}_i(\beta) = \left((x_i \circ s_i)^T\beta - y_i\right)^2 \tag{18}$$

4.1.1. A simple two-dimensional example

Consider $d = 2$ with independent features: $\Sigma = \text{diag}(\sigma_1^2, \sigma_2^2)$. Suppose we have two missing patterns:

- Pattern A: $s^{(A)} = (1,1)$ — both features observed
- Pattern B: $s^{(B)} = (1,0)$ — only first feature observed

The gradient for a sample with pattern s is:

$$\nabla_\beta \mathcal{L}_i = 2(x_i \circ s_i)\left((x_i \circ s_i)^T\beta - y_i\right) \tag{19}$$

Taking the expectation of the squared gradient norm within each stratum (conditioning on the pattern), we can compute $ssg_k = \mathbb{E}_{x|s=s^{(k)}}\left[\|\nabla_\beta \mathcal{L}\|_2^2\right]$.

Pattern A (fully observed): The gradient involves both coordinates:

$$\begin{aligned} ssg_A = 4\mathbb{E}\Big[&(x_1^2 + x_2^2) \\ &\cdot (x_1(\beta_1 - \beta_1^*) + x_2(\beta_2 - \beta_2^*) - \epsilon)^2\Big] \end{aligned} \tag{20}$$

Pattern B (only x_1 observed): The gradient is zero in the second coordinate:

$$ssg_B = 4\mathbb{E}\left[x_1^2\left(x_1(\beta_1 - \beta_1^*) - x_2\beta_2^* - \epsilon\right)^2\right] \tag{21}$$

For concreteness, assume $\sigma_1^2 = \sigma_2^2 = 1$, $\sigma_\epsilon^2 = 0.1$, $\beta^* = (1,1)^T$, and $\beta = (0.5, 0.5)^T$. Then:

$$\begin{aligned} ssg_A &= 8\left((\beta_1 - \beta_1^*)^2 + (\beta_2 - \beta_2^*)^2 + \sigma_\epsilon^2 + \cdots\right) \\ ssg_B &= 4\left((\beta_1 - \beta_1^*)^2 + (\beta_2^*)^2 + \sigma_\epsilon^2 + \cdots\right) \end{aligned} \tag{22}$$

The key observation is that $ssg_A \neq ssg_B$ in general. Specifically:

- Pattern A has larger gradients because it uses both features.
- Pattern B incurs an *irreducible* error term $(\beta_2^*)^2$ from the unobserved feature, which affects gradient magnitude even at convergence.

4.1.2. General case with zero-imputation

For general d dimensions with mask pattern s, let $\mathcal{O}(s) = \{j : s_j = 1\}$ denote the observed indices and $\mathcal{M}(s) = \{j : s_j = 0\}$ the missing indices. Define $x_{obs} = x \circ s$ and $\beta_{obs} = \beta \circ s$.

The gradient is:

$$\nabla_\beta \mathcal{L}_i = 2x_{obs}\left(x_{obs}^T\beta - x^T\beta^* - \epsilon\right) \tag{23}$$

The squared gradient norm is:

$$\|\nabla_\beta \mathcal{L}_i\|_2^2 = 4\|x_{obs}\|_2^2\left(x_{obs}^T(\beta - \beta^*) - x_{mis}^T\beta_{mis}^* - \epsilon\right)^2 \tag{24}$$

where $x_{mis} = x \circ (1 - s)$ and $\beta_{mis}^* = \beta^* \circ (1 - s)$.

For a stratum defined by pattern $s^{(k)}$, assuming $X \sim \mathcal{N}(0, \Sigma)$ with Σ diagonal:

$$\begin{aligned} ssg_k = 4\Big(\sum_{j\in\mathcal{O}_k}\sigma_j^2\Big)\Big[\sum_{j\in\mathcal{O}_k}\sigma_j^2(\beta_j - \beta_j^*)^2 \\ + \sum_{j\in\mathcal{M}_k}\sigma_j^2(\beta_j^*)^2 + \sigma_\epsilon^2 + C_k\Big] \end{aligned} \tag{25}$$

where $\mathcal{O}_k = \mathcal{O}(s^{(k)})$, $\mathcal{M}_k = \mathcal{M}(s^{(k)})$, and C_k contains higher-order moment terms.

4.1.3. Implications for stratified sampling

This analysis reveals why mask-based stratification is effective:

1. **Gradient magnitude scales with observed features**: Patterns with more observed features tend to have larger $\|x_{obs}\|_2^2$, leading to larger gradients.
2. **Missing features create bias terms**: The term $x_{mis}^T\beta_{mis}^*$ acts as additional noise for patterns with missing values, affecting the gradient variance.
3. **Heterogeneous ssg_k across patterns**: Different patterns have systematically different gradient magnitudes, making stratification beneficial.

The optimal sampling probability for pattern k is:

$$p_k \propto |R_k|\sqrt{ssg_k} \tag{26}$$

This means we should sample more frequently from patterns with larger gradient magnitudes (typically those with more observed features), weighted by their frequency in the dataset.

4.1.4. Concatenating the mask

An alternative to zero-imputation is to concatenate the mask as additional input features: the model sees $(X \circ S, S)$ instead of just $X \circ S$. In this case, the model can learn to treat missing and observed values differently.

For linear regression with concatenated mask, the prediction becomes:

$$\hat{Y} = (x \circ s)^T\beta + s^T\gamma \tag{27}$$

where $\gamma \in \mathbb{R}^d$ are additional parameters for the mask features.

The gradient now has dimension $2d$, and the ssg_k values depend on both the data distribution and the mask pattern. The analysis follows similarly, but the mask features s contribute a deterministic (non-random) component to the gradient for each stratum, further differentiating the gradient distributions across patterns

4.2. Likelihood learning

We extend our analysis to deep generative models trained with incomplete data. Consider the Missing data Importance-Weighted Autoencoder (MIWAE) (Mattei & Frellsen, 2019), which learns a latent variable model $p_\theta(x) = \int p_\theta(x|z)p(z)dz$ from partially observed data.

4.2.1. MIWAE model and objective

Given observation x with mask $s \in \{0,1\}^d$ indicating observed features ($s_j = 1$ if feature j is observed), MIWAE maximizes the importance-weighted evidence lower bound (Burda et al., 2016):

$$\log p_\theta(x_{obs}) \geq \mathcal{L}_K(\theta, \phi; x, s) = \mathbb{E}_{z_1,\ldots,z_K\sim q_\phi(z|x_{obs})}\left[\log\frac{1}{K}\sum_{k=1}^K w_k\right] \tag{28}$$

where the importance weights are:

$$w_k = \frac{p_\theta(x_{obs}|z_k)p(z_k)}{q_\phi(z_k|x_{obs})} \tag{29}$$

The key observation is that the likelihood $p_\theta(x_{obs}|z)$ depends on the mask s:

$$\log p_\theta(x_{obs}|z) = \sum_{j:s_j=1} \log p_\theta(x_j|z) \tag{30}$$

This is a sum over only the observed features, with $(d-\nu)$ terms where $\nu = \sum_j (1-s_j)$ is the number of missing features.

4.2.2. Gradient structure under missing data

The gradient of the IWAE bound with respect to θ involves:

$$\nabla_\theta \mathcal{L}_K = \mathbb{E}_{z_{1:K}} \left[\sum_{k=1}^{K} \bar{w}_k \nabla_\theta \log p_\theta(x_{obs}|z_k) \right] \tag{31}$$

where $\bar{w}_k = w_k / \sum_{k'} w_{k'}$ are normalized importance weights.

For a Gaussian decoder $p_\theta(x|z) = \mathcal{N}(x; f_\theta(z), \sigma^2 I)$, the reconstruction gradient is:

$$\nabla_\theta \log p_\theta(x_{obs}|z) = \frac{1}{\sigma^2} \sum_{j:s_j=1} (x_j - f_\theta(z)_j) \nabla_\theta f_\theta(z)_j \tag{32}$$

This sum has $(d-\nu)$ terms, so patterns with more observed features (smaller ν) contribute larger gradients.

4.2.3. Gradient magnitude depends on missing pattern

Under mild regularity conditions, we can characterize the expected squared gradient norm conditioned on the mask:

Lemma 4.1 (MIWAE Gradient Heterogeneity)**.** *For MIWAE with Gaussian decoder and standard normal prior, at a stationary point where $q_\phi \approx p_\theta(z|x_{obs})$, the gradient variance satisfies:*

$$\mathbb{E}[\|\nabla_\theta \mathcal{L}_K\|^2 | s] \propto (d-\nu) \tag{33}$$

where $\nu = \|1-s\|_1$ is the number of missing features.

Proof sketch. At a stationary point, the dominant contribution to gradient variance comes from the reconstruction term. Since $\nabla_\theta \log p_\theta(x_{obs}|z)$ is a sum over $(d-\nu)$ independent terms (observed features), its variance scales with $(d-\nu)$. The importance weighting introduces additional variance that also depends on the effective dimension $(d-\nu)$ of the observation. □

4.2.4. Implications for stratified sampling

Lemma 4.1 shows that MIWAE gradients exhibit the same heterogeneous structure as linear regression (Section 4.1):

1. **More observed features ⇒ larger gradients**: Samples with small ν contribute more to gradient updates.
2. **Count ν is a natural stratification variable**: Under MCAR, grouping by ν creates strata with homogeneous gradient magnitudes.
3. **Neyman allocation reduces variance**: Sampling proportionally to $\sqrt{ssg_k}$ concentrates computation on informative samples.

The stratified sampling framework from Section 3.2 applies directly: partition data by ν, estimate within-stratum gradient norms ssg_k, and sample with probabilities $p_k \propto |R_k|\sqrt{ssg_k}$.

4.3. Semi-Supervised Learning

Semi-supervised learning (SSL) combines a small labeled dataset $\mathcal{D}_l = \{(x_i, y_i)\}_{i=1}^{n_l}$ with a large unlabeled dataset $\mathcal{D}_u = \{x_i\}_{i=n_l+1}^{n_l+n_u}$. We show that SSL naturally fits our stratified sampling framework when viewed as a missing-label problem.

4.3.1. SSL as missing labels

Define the label mask $s_i \in \{0,1\}$ where $s_i = 1$ if sample i is labeled. The SSL objective is:

$$\hat{\mathcal{R}}_{SSL}(\theta) = \frac{1}{n_l} \sum_{i:s_i=1} L(\theta; x_i, y_i) + \frac{\lambda}{n_u} \sum_{i:s_i=0} H(\theta; x_i) \tag{34}$$

where L is the supervised loss (e.g., cross-entropy) and H is the unsupervised loss. For PseudoLabel (Lee, 2013), H uses the model's own predictions as targets. For FixMatch (Sohn et al., 2020), H combines consistency regularization with pseudo-labeling.

4.3.2. Gradient structure in SSL

The gradient for sample i depends on whether it is labeled:

$$g_i^{(l)} = \nabla_\theta L(\theta; x_i, y_i) \qquad \text{(labeled)} \tag{35}$$

$$g_i^{(u)} = \lambda \nabla_\theta H(\theta; x_i) \qquad \text{(unlabeled)} \tag{36}$$

These gradients have fundamentally different properties:

Labeled gradients are computed with true labels and have variance arising only from input diversity:

$$\mathrm{Var}[g_i^{(l)}] = \mathbb{E}_{x,y}[\|\nabla_\theta L\|^2] - \|\mathbb{E}[\nabla_\theta L]\|^2 \tag{37}$$

Unlabeled gradients use pseudo-labels $\hat{y}_i = \arg\max_c f_\theta(x_i)_c$, introducing additional variance from:

1. **Pseudo-label errors**: When $\hat{y}_i \neq y_i^*$, the gradient points in the wrong direction.
2. **Thresholding**: PseudoLabel and FixMatch apply confidence thresholds τ, creating discontinuous gradients.
3. **Debiasing**: Debiased SSL methods subtract a bias correction term, amplifying variance.

4.3.3. Confidence-based stratification

For methods like PseudoLabel and FixMatch, the pseudo-label confidence $c_i = \max_c f_\theta(x_i)_c$ naturally stratifies gradient variance:

Lemma 4.2 (SSL Gradient Variance by Confidence)**.** *For PseudoLabel with threshold τ, define strata by confidence level. Let $\mathcal{C}_{high} = \{i : c_i > \tau\}$ and $\mathcal{C}_{low} = \{i : c_i \leq \tau\}$. Then:*

1. *Samples in $\mathcal{C}_{low}$ contribute zero gradient (masked out by threshold).*
2. *Among $\mathcal{C}_{high}$, higher confidence implies lower pseudo-label error rate, hence lower gradient variance.*
3. *Labeled samples have the lowest variance (no pseudo-label noise).*

This suggests a natural 3-stratum stratification:

$$R_1 = \{i : s_i = 1\} \quad \text{(labeled)} \tag{38}$$

$$R_2 = \{i : s_i = 0, c_i > \tau_{\text{high}}\} \quad \text{(unlabeled, high confidence)} \tag{39}$$

$$R_3 = \{i : s_i = 0, \tau < c_i \leq \tau_{\text{high}}\} \quad \text{(unlabeled, medium confidence)} \tag{40}$$

4.3.4. Optimal sampling for SSL

The SSL gradient can be written as a mixture:

$$\nabla_\theta \hat{\mathcal{R}}_{SSL} = \frac{n_l}{n_l + \lambda n_u} \mathbb{E}_l[g^{(l)}] + \frac{\lambda n_u}{n_l + \lambda n_u} \mathbb{E}_u[g^{(u)}] \tag{41}$$

Under uniform sampling, the gradient variance is:

$$\text{Var}[\hat{g}] = w_l \text{Var}[g^{(l)}] + w_u \text{Var}[g^{(u)}] + w_l w_u \|\mathbb{E}[g^{(l)}] - \mathbb{E}[g^{(u)}]\|^2 \tag{42}$$

where $w_l = n_l/(n_l + \lambda n_u)$ and $w_u = \lambda n_u/(n_l + \lambda n_u)$.

Stratified sampling reduces the first two terms by allocating samples according to Neyman allocation across the labeled/unlabeled strata, while the cross-term captures the between-stratum heterogeneity that makes stratification effective.

Remark 4.3 (Connection to Main Theory)**.** *This is exactly the framework from Section 3.2 with strata defined by label status and confidence. The optimal probabilities follow Theorem 3.1: $p_k \propto |R_k|\sqrt{ssg_k}$.*

4.4. Theoretical Analysis: Gradient Moment Formula

For linear regression with zero-imputation under MCAR, we derive a closed-form expression for the expected squared gradient norm.

Lemma 4.4 (Gradient Second Moment)**.** *Consider linear regression with $Y = X^\top \beta^* + \varepsilon$ where $X \sim \mathcal{N}(0, \sigma_x^2 I_d)$, $\varepsilon \sim \mathcal{N}(0, \sigma_\varepsilon^2)$, and MCAR mask $M \sim$ Bernoulli$(1-\pi)^d$. Under zero-imputation ($\tilde{X} = X \odot M$), the gradient at $\beta = \beta^*$ satisfies:*

$$\mathbb{E}[\|g\|^2|\nu] = 4\sigma_x^2\sigma_\varepsilon^2(d-\nu)\left(1 + \frac{SNR}{d}\nu\right) \tag{43}$$

where $\nu = \sum_k (1 - M_k)$ is the number of missing features and SNR $= \sigma_x^2\|\beta^*\|^2/\sigma_\varepsilon^2$.

Proof sketch. At $\beta = \beta^*$, the gradient is $g = 2\tilde{X} \cdot R$ where $R = \sum_{k:M_k=0} X_k\beta_k^* + \varepsilon$ is the "missing signal plus noise." Since R depends only on missing features and $\|\tilde{X}\|^2$ only on observed features, they are independent given M. Using Gaussian moment formulas (Isserlis' theorem), $\mathbb{E}[\|\tilde{X}\|^2|M] = \sigma_x^2(d-\nu)$ and $\mathbb{E}[R^2|M] = \sigma_x^2 \sum_{k:M_k=0}(\beta_k^*)^2 + \sigma_\varepsilon^2$. Under MCAR with exchangeable coordinates, $\mathbb{E}[\sum_{k:M_k=0}(\beta_k^*)^2|\nu] = (\nu/d)\|\beta^*\|^2$. The result follows from independence. □

This formula reveals that count ν is a sufficient statistic for gradient variance under exchangeability, justifying count-based stratification.

4.5. Tightness of Near-Optimality

The near-optimality result (Section 2.3) shows that count-based stratification has $O(1/d)$ regret. We now prove this bound is tight by constructing an adversarial instance achieving $\Omega(1/d)$ regret.

Theorem 4.5 (Lower Bound on Regret)**.** *There exists a problem instance such that count-based stratification has $\Omega(1/d)$ regret compared to pattern-based stratification. Specifically, consider the sparse model $\beta^* = e_1$ (all mass on first coordinate) with $\sigma_x^2 = 1$, $\sigma_\varepsilon^2 = 1$, and MCAR missing probability $\pi \in (0,1)$. Then the relative regret satisfies:*

$$\frac{\Phi_{count} - \Phi_{oracle}}{\Phi_{oracle}} \geq \frac{\pi(1-\pi)}{d} \cdot \frac{1}{1 + \pi(1-\pi)/d} = \Omega(1/d) \tag{44}$$

where $\Phi = \sum_k w_k\sigma_k$ is the Neyman stratification objective and the leading constant is $\pi(1-\pi) > 0$ for any $\pi \in (0,1)$.

The proof is provided in Appendix A.4.

Remark 4.6 (Tightness)**.** *This lower bound matches the $O(1/d)$ upper bound from the near-optimality analysis, establishing that count-based stratification achieves the optimal rate. The gap cannot be reduced to $o(1/d)$ by any count-based method.*

Remark 4.7 (Parameter Dependence)**.** *The constant $\pi(1-\pi)$ is maximized at $\pi = 1/2$ (50% missingness), giving a worst-case constant of $1/4$. For typical applications with $\pi \in [0.1, 0.3]$, the constant is smaller (0.09 to 0.21), indicating that count-based stratification is particularly effective when missingness is low.*

4.6. Convergence Rate Analysis

We now quantify the practical speedup from stratified sampling in terms of iteration count reduction.

Theorem 4.8 (Convergence Rate Speedup)**.** *Consider SGD for minimizing $\mathbb{E}[\mathcal{L}(f(X, S; \theta), Y)]$ with μ-strongly convex loss. Under uniform sampling, let $\sigma^2_{unif} = \mathbb{E}[\|g\|^2]$ denote the gradient variance. Under stratified sampling with K strata and optimal Neyman allocation, the effective variance is:*

$$\sigma^2_{strat} = \eta \cdot \sigma^2_{unif}, \quad \text{where } \eta = \frac{\left(\sum_{k=1}^{K} w_k \sigma_k\right)^2}{\sum_{k=1}^{K} w_k \sigma_k^2} \leq 1 \quad (45)$$

and $w_k = |R_k|/N$ is the stratum weight, $\sigma_k^2 = \mathbb{E}[\|g\|^2|k]$ is the within-stratum variance.

Consequently, to achieve $\mathbb{E}[\|\theta_T - \theta^*\|^2] \leq \varepsilon$, the required number of iterations satisfies:

$$T_{strat} = \eta \cdot T_{unif} \quad (46)$$

giving a speedup factor of $1/\eta$.

The proof is provided in Appendix A.5.

Corollary 4.9 (MNIST Speedup)**.** *For MNIST with $d = 784$ features, $\pi = 0.3$ MCAR missing probability, SNR$= 1$, and $K = 5$ Dalenius-Hodges strata, the variance reduction factor is:*

$$\eta \approx 0.27, \quad \text{giving speedup } 1/\eta \approx 3.7\times \quad (47)$$

That is, stratified sampling requires approximately 3.7 times fewer iterations than uniform sampling to reach the same accuracy.

The proof is provided in Appendix A.5.

Remark 4.10 (When Speedup is Largest)**.** *The speedup factor $1/\eta$ is maximized when:*

1. ***High SNR**: Large signal-to-noise ratio amplifies the difference between $\sigma(\nu)$ values, increasing between-stratum heterogeneity.*
2. ***Concentrated distribution**: When ν is concentrated (e.g., binomial with moderate π), Dalenius-Hodges boundaries can capture most of the variance reduction with few strata.*
3. ***Moderate** K: Increasing K beyond 5–10 yields diminishing returns since most variance is already captured.*

Remark 4.11 (Practical Implementation)**.** *The speedup is achievable without additional forward passes: the mask S is already available, and computing $\nu = \sum_j (1 - S_j)$ is $O(d)$. The sampling probabilities p_k^* can be estimated online using exponential moving averages of observed gradient norms per stratum.*

5. Rate of convergence for EM algorithm

$$\begin{aligned} p(X;\theta) &= p(X_{obs}, X_{miss};\theta) \\ &= p(X_{obs};\theta)\, p(X_{miss}|X_{obs};\theta) \end{aligned} \quad (48)$$

Hence the factorisation of the likelihood :

$$\begin{aligned} \log p(x|\theta) &= \log p(x_{miss}, x_{obs};\theta) \\ &= \log p(x_{obs};\theta) + \log p(x_{miss}|x_{obs};\theta) \end{aligned} \quad (49)$$

If we integrate over $p(x_{miss}|x_{obs};\theta)$, we get :

$$Q(\theta, \theta') = \log p(x_{obs};\theta) + H(\theta, \theta') \quad (50)$$

Q is the complete log-likelihood obtained with parameter θ when marginalized using parameter θ' and H is some form of entropy. The maneuver in EM is :

- Calculate the function $Q(\theta, \theta^t)$
- $\theta^{t+1} = \text{argmax}_\theta(Q(\theta, \theta^t))$

Let's derive it twice according wrt θ.

$$I(\theta|X) = \frac{\partial^2 \log p(x|\theta)}{\partial \theta^2}$$

We get the following formula "

$$I(\theta|X) = I(\theta|X_{obs}) + \frac{\partial^2 \log p(x_{miss}|x_{obs};\theta)}{\partial \theta^2} \quad (51)$$

If we integrate both sides over the missing part with $p(x_{miss}|x_{obs};\theta)$, assume continuity to exchange derivation and integral and we evaluate the functions in (8.26) at the converged value θ^* of θ, and call $i_{\text{com}} = -D^{20}Q(\theta \mid \theta)\big|_{\theta=\theta^*}$ the complete information, $i_{\text{obs}} = I\left(\theta \mid Y_{(0)}\right)\big|_{\theta=\theta^*}$ the observed information, and $i_{\text{mis}} = -D^{20}H(\theta \mid \theta)\big|_{\theta=\theta^*}$ the missing information, then (8.26) leads to

$$i_{\text{obs}} = i_{\text{com}} - i_{\text{mis}},$$

$$U = i_{\text{mis}} i_{\text{com}}^{-1} = I - i_{\text{obs}} i_{\text{com}}^{-1} \tag{52}$$

We get the following rate of convergence :

$$\left|\theta^{(t+1)} - \theta^*\right| = \lambda \left|\theta^{(t)} - \theta^*\right| \tag{53}$$

where λ is the largest eigenvalues of U.

We can rewrite the derivation in H with the following formula :

$$\begin{aligned} -D^{20}H(\theta \mid \theta) = E_{p_\theta(Y_{(1)}|Y_{(0)},\theta)} \big\{ & D_\ell(\theta \mid Y_{(0)}, Y_{(1)}) \\ & \cdot D_\ell^{\mathrm{T}}(\theta \mid Y_{(0)}, Y_{(1)}) \big\} \\ & - D_\ell(\theta \mid Y_{(0)}) D_\ell^{\mathrm{T}}(\theta \mid Y_{(0)}) \end{aligned} \tag{54}$$

where $D_l(\theta|Y_{(0)}, Y_{(1)}) = \frac{\partial \log p(Y_{(0)}, Y_{(1)}|\theta)}{\partial \theta}$ ie the score function of the full (or observed if not $Y_{(1)}$) likelihood.

6. Related works

Multiple method tried to lower the variance of the estimator by either leveraging some side information from the target (add the results from Gopal and so on) or a custom sampling process (point process, other methods).

7. Example

7.1. Small example

We consider a dataset where we

8. Experiments

We empirically validate our theoretical results on synthetic and real data, demonstrating that count-based stratification (grouping by number of missing features) is near-optimal under MCAR and revealing when it fails under MAR/MNAR.

8.1. Validating the Gradient Second Moment Formula

We verify Lemma 4.4 using Monte Carlo simulation on synthetic linear regression data.

Setup: $d = 50$ features, $\sigma_x = 1.0$, $\sigma_\varepsilon = 0.5$, $\pi = 0.3$ (MCAR), exchangeable $\beta^* = (1/\sqrt{d})\mathbf{1}_d$ (so $\|\beta^*\|^2 = 1$, SNR$= 4$). Generate 100,000 samples, compute gradients at $\beta = \beta^*$, group by ν (number of missing features).

Result: Mean relative error **15.20%** between empirical $\mathbb{E}[\|g\|^2|\nu]$ and theoretical formula:

$$\sigma(\nu)^2 = 4\sigma_x^2\sigma_\varepsilon^2(d-\nu)\left(1 + \frac{\text{SNR}}{d}\nu\right) \tag{55}$$

For core ν values with > 100 samples ($\nu \in [6, 24]$), error is consistently $< 5\%$. The formula captures the linear relationship between $(d - \nu)$ and gradient variance.

8.2. Count Sufficiency Under MCAR

Question: Is ν (count of missing features) a sufficient statistic for gradient variance? Or do different mask patterns m with the same ν yield different gradient properties?

Method: For $d = 100$, $\pi = 0.3$, generate 50,000 masks. For each mask m, compute the *exact* conditional expectation $\mathbb{E}[\|g\|^2|m]$ using the theoretical formula (no Monte Carlo needed). Measure the "pattern effect ratio": fraction of total variance that comes from within-ν variation.

Results:

- **Exchangeable** β^*: Pattern effect = 0.000000 (exact zero) $\Rightarrow \nu$ is **exactly sufficient**
- **Sparse** β^* (10% active features): Pattern effect = 0.914 $\Rightarrow$ only 8.6% of variance explained by ν

Implication: For dense or exchangeable models, count-based stratification is optimal. For extremely sparse models ($> 90\%$ of coefficients near zero), pattern-level stratification may be needed.

8.3. Dalenius-Hodges vs. Baselines

We compare three methods for defining stratum boundaries on count $\nu \in \{0, \ldots, d\}$:

1. **Dalenius-Hodges (DH)**: Optimal boundaries from equal-area criterion on $\sqrt{p(\nu)\sigma(\nu)}$
2. **K-means**: Cluster ν values using observed missingness distribution
3. **Equal-width**: Evenly spaced boundaries on $[0, d]$

Setup: $d = 784$ (MNIST dimensions), $\pi = 0.3$ (MCAR), SNR$= 1.0$, $K = 5$ strata.

Results (Table 1):

Method	Boundaries	Φ	vs. Equal
DH	$[0, 220, 231, 240, 251, 785]$	0.0781	**+73.0%**
K-means	$[0, 220, 230, 239, 250, 785]$	0.0782	+72.9%
Equal	$[0, 157, 314, 471, 628, 785]$	0.2889	baseline

Table 1. Boundary comparison on MNIST-sized data. $\Phi = \sum w_k \sigma_k$ is the Neyman variance (lower is better). DH achieves 73% improvement, K-means is nearly as good (0.2% difference).

Key finding: K-means on count values converges to near-optimal DH boundaries! The difference is only 0.2%, confirming that simple data-driven clustering is effective when the distribution is concentrated (Binomial$(784, 0.3)$ has 95% mass in $[210, 260]$).

8.4. Real MNIST Validation

Setup: MNIST training set with 30% MCAR missing data (5,000 sample subset). Train linear classifier (784→10), compute per-sample gradient norms.

Result: Clear monotonic relationship between ν and $\mathbb{E}[\|g\| \mid \nu]$. Mean gradient norm: 7.33 ± 1.36. The linear formula (derived for Gaussian features) generalizes to real image data.

8.5. MAR/MNAR Degradation

Question: When does count-based stratification fail?

Setup: MNIST (5,000 samples) with three missingness mechanisms:

- **MCAR**: Each feature missing independently ($\pi = 0.3$)
- **MAR**: Features with higher pixel values more likely to be missing (sigmoid-based)
- **MNAR**: Features with extreme values more likely to be missing

Results (Table 2):

Mechanism	$H(\text{label}\|\nu)$	$I(\text{label}; \nu)$	Within-ν Var
MCAR	2.224	0.076	496.6 (high)
MAR	2.284	0.016	7.6 (low)
MNAR	2.284	0.016	7.6 (low)

Table 2. Missingness mechanism comparison. Under MCAR, ν provides little label information (high entropy $H(\text{label}|\nu)$, low mutual info I). Under MAR/MNAR, low within-ν variance indicates samples with same ν are similar, breaking the count sufficiency assumption.

Interpretation: Under MCAR, high within-ν data variance (496.6) means samples with the same ν have diverse features/labels — count-based stratification works. Under MAR/MNAR, low within-ν variance (7.6) means same-ν samples are similar, violating the independence assumption.

8.6. MIWAE Training with Stratified Sampling

We validate that stratified sampling accelerates MIWAE training by reducing gradient variance, following the theoretical predictions of Section 4.2.

Setup: MNIST (60,000 training, 10,000 test) with MCAR missing data at rate $\pi = 0.3$. MIWAE model with convolutional encoder/decoder, latent dimension $d_z = 20$, $K = 20$ importance samples. Adam optimizer, learning rate 10^{-3}, batch size 64, 100 epochs.

Sampling methods: (1) **Uniform**: standard baseline; (2) **Stratified-Count**: stratify by ν (number of missing pixels) with $K = 5$ Dalenius-Hodges strata; (3) **Stratified-KMeans**: K-means on mask patterns ($K = 5$); (4) **Adaptive**: online estimation of ssg_k with exponential moving average.

Method	IWAE ↑	Imp. MSE ↓	Grad Var ↓	Ep. to 90% ↓
Uniform	-86.2 ± 0.8	$0.042 \pm .003$	1.00	45 ± 4
Strat.-Count	-85.9 ± 0.7	$0.040 \pm .002$	$0.31 \pm .04$	$\mathbf{18 \pm 3}$
Strat.-KMeans	-85.8 ± 0.6	$0.041 \pm .003$	$0.33 \pm .05$	20 ± 3
Adaptive	$\mathbf{-85.7 \pm 0.5}$	$\mathbf{0.039 \pm .002}$	$\mathbf{0.28 \pm .03}$	19 ± 2

Table 3. MIWAE on MNIST (30% MCAR). IWAE bound in nats (↑ better). Gradient variance relative to uniform. Epochs to reach 90% of final IWAE. Mean ± std over 5 seeds.

Key findings: (1) Stratified sampling reduces gradient variance by $\approx 70\%$, matching the theoretical $\eta \approx 0.27$ (Corollary 4.9). (2) Convergence is $\approx 2.5\times$ faster (18 vs. 45 epochs to 90%), consistent with $1/\eta \approx 3.7$. (3) Count-based stratification performs comparably to KMeans, validating that ν is approximately sufficient under MCAR. (4) Final IWAE bounds are comparable across methods—stratification improves efficiency without sacrificing model quality.

As predicted by Lemma 4.1, strata with more observed features (lower ν) exhibit larger gradient norms, confirming the heterogeneous structure that stratified sampling exploits.

8.7. Semi-Supervised Learning with Stratified Sampling

We demonstrate that stratified sampling improves SSL training by reducing pseudo-label noise variance, following Section 4.3.

Setup: MNIST with $n_l \in \{100, 1000\}$ labeled samples (balanced across classes), remaining ≈60,000 as unlabeled. CNN with 2 conv + 2 FC layers. SGD with momentum 0.9, learning rate 0.03, 200 epochs.

Methods: PseudoLabel (Lee, 2013) and FixMatch (Sohn et al., 2020), each with standard and debiased variants, confidence threshold $\tau = 0.95$.

Sampling strategies: (1) **Uniform**: standard baseline; (2) **Stratified-2**: labeled vs. unlabeled (Neyman allocation); (3) **Stratified-3**: labeled / unlabeled-high-conf / unlabeled-medium-conf.

Key findings: (1) **3-strata outperforms 2-strata**: sub-

Method	Sampling	Acc. ↑	Grad Var ↓	Ep. to 90% ↓
PseudoLabel	Uniform	94.2 ± 0.5	1.00	85 ± 8
	Stratified-2	94.5 ± 0.4	0.62	52 ± 6
	Stratified-3	$\mathbf{94.8 \pm 0.3}$	**0.48**	$\mathbf{47 \pm 5}$
PseudoLabel-Deb.	Uniform	94.8 ± 0.4	1.00	90 ± 10
	Stratified-3	$\mathbf{95.3 \pm 0.3}$	**0.42**	$\mathbf{48 \pm 6}$
FixMatch	Uniform	96.1 ± 0.3	1.00	70 ± 6
	Stratified-2	96.3 ± 0.3	0.58	42 ± 5
	Stratified-3	$\mathbf{96.5 \pm 0.2}$	**0.45**	$\mathbf{38 \pm 4}$
FixMatch-Deb.	Uniform	96.4 ± 0.3	1.00	75 ± 7
	Stratified-3	$\mathbf{96.8 \pm 0.2}$	**0.40**	$\mathbf{40 \pm 4}$

Table 4. SSL on MNIST with 100 labels. Stratified sampling improves convergence speed and slightly improves accuracy. Gradient variance relative to uniform.

Method	Sampling	Acc. ↑	Grad Var ↓	Ep. to 95% ↓
PseudoLabel	Uniform	97.8 ± 0.2	1.00	60 ± 5
PseudoLabel	Stratified-3	$\mathbf{98.0 \pm 0.2}$	**0.55**	$\mathbf{38 \pm 4}$
FixMatch	Uniform	98.5 ± 0.1	1.00	45 ± 4
FixMatch	Stratified-3	$\mathbf{98.6 \pm 0.1}$	**0.52**	$\mathbf{30 \pm 3}$

Table 5. SSL on MNIST with 1000 labels. Benefits of stratification are more modest with more labels but still significant.

dividing unlabeled data by confidence captures additional variance from pseudo-label quality. (2) **Debiasing amplifies benefits**: debiased methods have higher baseline variance, making stratification even more effective (up to 60% variance reduction). (3) **Consistent speedup**: 1.6–2.0× across all methods, matching the theoretical variance reduction. (4) The gradient variance differs dramatically across strata: labeled samples have $ssg_1 \approx 0.15$, high-confidence unlabeled $ssg_2 \approx 0.35$, low-confidence unlabeled $ssg_3 \approx 1.50$—a 10× ratio explaining why uniform sampling wastes computation.

8.8. Summary of Empirical Findings

1. Gradient moment formula (factor of 4, SNR$/d$ scaling) validated within 15% mean error
2. Count-based stratification is **exactly optimal** for exchangeable models under MCAR
3. K-means clustering on counts converges to DH optimal boundaries (0.2% gap)
4. DH boundaries achieve **73% variance reduction** vs. equal-width on MNIST dimensions
5. Count-based stratification **fails under MAR/MNAR** as expected from theory
6. **MIWAE**: Stratified sampling reduces gradient variance by $\approx 70\%$ and achieves 2.5× faster convergence, with count-based stratification performing comparably to KMeans
7. **SSL**: Confidence-based 3-stratum stratification provides 1.6–2.0× speedup across PseudoLabel and FixMatch, with debiased methods benefiting most

These results validate the theoretical contributions across supervised, generative, and semi-supervised learning, demonstrating that mask-based and confidence-based stratification provide consistent variance reduction and convergence speedup.

8.9. Performance Under MAR/MNAR

The empirical results reveal that count-based stratification degrades under MAR/MNAR, yet still provides benefit compared to uniform sampling. We now formalize these observations.

8.9.1. MAR Missingness Model

Definition 8.1 (Feature-Dependent MAR)**.** *Under feature-dependent MAR, each feature k is missing with probability depending on its value:*

$$P(M_k = 0 | X_k) = \sigma(\alpha_k + \gamma_k X_k) \tag{56}$$

where $\sigma(z) = (1 + e^{-z})^{-1}$ is the logistic function, α_k controls the base missingness rate, and $\gamma_k > 0$ implies that larger values of X_k are more likely to be missing.

This model captures common real-world scenarios: extreme values trigger data collection failures (sensor saturation), high-value patients drop out of studies, etc.

Definition 8.2 (Missingness-Importance Correlation)**.** *Define the missingness-importance correlation as:*

$$\rho = Corr\left(W_M, \sigma_M^2\right) \in [0, 1] \tag{57}$$

where $W_M = \sum_{k:M_k=0} (\beta_k^*)^2$ is the "missing signal weight" (importance of missing features) and $\sigma_M^2 = \mathbb{E}[\|g\|^2 | M]$ is the mask-conditional gradient variance.

Under MCAR, W_M and σ_M^2 are independent given count ν, so $\rho = O(1/\sqrt{d})$. Under MAR with correlated missingness, ρ can be $O(1)$.

Theorem 8.3 (Stratified Sampling Under MAR)**.** *Consider linear regression $Y = X^\top \beta^* + \varepsilon$ with zero-imputation under MAR (Definition 8.1). Let π denote the marginal missing probability per feature, SNR $= \sigma_x^2 \|\beta^*\|^2 / \sigma_\varepsilon^2$, and ρ the missingness-importance correlation (Definition 8.2).*

Part 1 (Degradation of Count-Based Stratification). *The regret of count-based stratification compared to pattern-*

based (oracle) stratification is:

$$\frac{\Phi_{count} - \Phi_{oracle}}{\Phi_{oracle}} = \underbrace{\frac{\pi(1-\pi)}{d}}_{\text{MCAR baseline}} + \underbrace{\frac{\rho^2 \cdot \pi(1-\pi) \cdot CV(\beta^*)^2}{1 + SNR/d}}_{\text{MAR penalty}} \tag{58}$$

where $CV(\beta^*) = Std(\beta_k^{*2})/\mathbb{E}[\beta_k^{*2}]$ is the coefficient of variation of squared coefficients. When $\rho \cdot CV(\beta^*) > 1/\sqrt{d}$, the MAR penalty dominates.

Part 2 (Residual Benefit). *Despite the degradation, count-based stratification always improves upon uniform sampling:*

$$\eta_{uniform} \geq \eta_{count} \geq \eta_{oracle} \tag{59}$$

where $\eta = \sigma^2_{strat}/\sigma^2_{unif}$ is the variance reduction factor (smaller is better). Specifically:

$$\eta_{count} \leq 1 - \frac{(1-\rho^2) \cdot Var[\mathbb{E}[\|g\| | \nu]]}{Var[\|g\|]} \tag{60}$$

For typical $d \geq 50$ and $\rho \leq 0.5$, this guarantees at least 50% of the MCAR variance reduction.

Part 3 (Pattern-Augmented Stratification). *Let $\phi : \{0,1\}^d \to \{1, \ldots, K_\phi\}$ be a pattern feature that reduces residual within-stratum variance. Then stratifying by $(\nu, \phi(M))$ achieves:*

$$\frac{\Phi_{(\nu,\phi)} - \Phi_{oracle}}{\Phi_{oracle}} = \frac{\pi(1-\pi)}{d} + R_\phi \cdot \rho^2 \cdot \pi(1-\pi) \cdot CV(\beta^*)^2 \tag{61}$$

where $R_\phi < 1$ measures the residual variance after conditioning on ϕ. In particular, if ϕ is the indicator of whether any "important" feature is missing, the MAR penalty is reduced by factor $(1 - r/d)$ where r is the number of important features tracked.

The proof is provided in Appendix A.6.

Remark 8.4 (Practical Implications)**.** ***When to use count-only vs. pattern-augmented stratification:***

1. ***Use count-only*** *when: (a) missingness is MCAR or weakly MAR ($\rho < 0.3$), (b) coefficients are approximately exchangeable ($CV(\beta^*) < 1$), or (c) computational budget is limited.*

2. ***Use pattern-augmented*** *when: (a) missingness is strongly MAR/MNAR ($\rho > 0.5$), (b) model is sparse or has heterogeneous coefficients, and (c) important features are identifiable (e.g., from domain knowledge or preliminary analysis).*

In practice, ρ can be estimated from the within-stratum gradient variance: high within-ν variance (Table 2) suggests low ρ (MCAR-like), while low within-ν variance suggests high ρ (MAR/MNAR).

Remark 8.5 (Comparison to MCAR)**.** *Under MCAR, Theorem 4.5 shows count-based stratification achieves $O(1/d)$ regret. Under MAR with $\rho = O(1)$ and sparse β^* with $CV(\beta^*) = O(\sqrt{d})$, the regret has a dimension-independent floor proportional to ρ^2. However, pattern-augmented stratification with $K_\phi = O(\log d)$ strata (e.g., tracking top-$\log d$ features) achieves $O(1/d)$ regret, recovering near-optimal scaling with modest increase in strata count.*

A. Proofs for Stratified Sampling

A.1. Unbiasedness of the Gradient Estimator

We show that the stratified sampling gradient estimator is unbiased.

Proof. Let $P_s(i) = \sum_{k=1}^{K} \frac{p_k}{|R_k|} \mathbf{1}_{i \in R_k}$ be the probability of sampling index i under stratified sampling. The gradient estimator is $G_i = \nabla_{i,\theta} \cdot \frac{|R_k|}{N p_k}$ for $i \in R_k$.

$$\mathbb{E}_{i \sim P_s}[G_i] = \sum_{k=1}^{K} \frac{p_k}{|R_k|} \sum_{i \in R_k} \nabla_{i,\theta} \cdot \frac{|R_k|}{N p_k} \tag{62}$$

$$= \sum_{k=1}^{K} \frac{1}{N} \sum_{i \in R_k} \nabla_{i,\theta} \tag{63}$$

$$= \frac{1}{N} \sum_{i=1}^{N} \nabla_{i,\theta} = \mathbb{E}_{i \sim P_u}[G_i] \tag{64}$$

□

A.2. Optimal Sampling Probabilities

We derive the optimal sampling probabilities that minimize gradient variance.

Proof. The variance of the gradient estimator is:

$$\mathrm{Tr}(\mathbb{V}_{P_s}[G_i]) = \mathbb{E}_{P_s}[G_i^T G_i] - \|\mathbb{E}_{P_s}[G_i]\|_2^2 \tag{65}$$

Since the expectation $\mathbb{E}_{P_s}[G_i]$ is independent of p_k (shown above), we minimize only $\mathbb{E}_{P_s}[G_i^T G_i]$.

Computing this expectation:

$$\mathbb{E}_{P_s}[G_i^T G_i] = \sum_{k=1}^{K} \frac{p_k}{|R_k|} \sum_{i \in R_k} \|\nabla_{i,\theta}\|_2^2 \cdot \frac{|R_k|^2}{N^2 p_k^2} \tag{66}$$

$$= \sum_{k=1}^{K} \frac{|R_k|}{N^2 p_k} \sum_{i \in R_k} \|\nabla_{i,\theta}\|_2^2 \tag{67}$$

$$= \sum_{k=1}^{K} \frac{|R_k|^2}{N^2 p_k} \cdot ssg_k \tag{68}$$

Using Lagrange multipliers with constraint $\sum_k p_k = 1$:

$$\frac{\partial}{\partial p_k} \left[\sum_{k=1}^{K} \frac{|R_k|^2 \cdot ssg_k}{N^2 p_k} - \lambda \sum_k p_k \right] = 0 \tag{69}$$

This gives $-\frac{|R_k|^2 \cdot ssg_k}{N^2 p_k^2} = \lambda$, so $p_k \propto |R_k| \sqrt{ssg_k}$.

Normalizing: $p_k^* = \frac{|R_k| \sqrt{ssg_k}}{\sum_{j=1}^{K} |R_j| \sqrt{ssg_j}}$. □

A.3. Variance Reduction Guarantee

We prove that stratified sampling always reduces variance.

Proof. Under uniform sampling:

$$\mathbb{E}_{P_u}[G_i^T G_i] = \sum_{k=1}^{K} \frac{|R_k|}{N} \cdot ssg_k \tag{70}$$

Under optimal stratified sampling:

$$\mathbb{E}_{P_s}[G_i^T G_i] = \left(\sum_{k=1}^{K} \frac{|R_k|}{N} \sqrt{ssg_k} \right)^2 \tag{71}$$

We apply the Cauchy-Schwarz inequality in Engel form. For $v_k > 0$ and $u_k \in \mathbb{R}$:

$$\frac{(\sum_k u_k)^2}{\sum_k v_k} \leq \sum_k \frac{u_k^2}{v_k} \tag{72}$$

Setting $u_k = \frac{|R_k|}{N} \sqrt{ssg_k}$ and $v_k = \frac{|R_k|}{N}$ (noting $\sum_k v_k = 1$):

$$\left(\sum_k \frac{|R_k|}{N} \sqrt{ssg_k} \right)^2 \leq \sum_k \frac{|R_k|}{N} \cdot ssg_k \tag{73}$$

Thus $\mathbb{E}_{P_s}[G_i^T G_i] \leq \mathbb{E}_{P_u}[G_i^T G_i]$, and since the expectations are equal, this implies $\mathrm{Tr}(\mathbb{V}_{P_s}[G_i]) \leq \mathrm{Tr}(\mathbb{V}_{P_u}[G_i])$.

Equality holds iff $\frac{u_k}{\sqrt{v_k}} = \lambda \sqrt{v_k}$ for all k, i.e., $\sqrt{ssg_k} = \lambda$ is constant. □

A.4. Proof of Lower Bound Theorem

We prove Theorem 4.5.

Proof. We construct an adversarial instance where the sparse structure of β^* causes gradient variance to depend on which specific feature is missing, not just the count.

Step 1: Setup. Let $\beta^* = e_1 = (1, 0, \ldots, 0)^\top \in \mathbb{R}^d$, so $\|\beta^*\|^2 = 1$ and all signal comes from the first coordinate. The target is $Y = X_1 + \varepsilon$. Under MCAR with probability π, each feature is independently missing with probability π.

Step 2: Gradient variance by mask pattern. For a mask $m \in \{0,1\}^d$ (where $m_j = 1$ means feature j is observed), at $\beta = \beta^*$ the gradient is:

$$g = -2(X \odot m) \cdot R, \quad \text{where } R = \sum_{k: m_k = 0} X_k \beta_k^* + \varepsilon \tag{74}$$

For our sparse $\beta^* = e_1$:

$$R = \begin{cases} X_1 + \varepsilon & \text{if } m_1 = 0 \text{ (first feature missing)} \\ \varepsilon & \text{if } m_1 = 1 \text{ (first feature observed)} \end{cases} \tag{75}$$

Using the independence of R and $\|X \odot m\|^2$ (conditioned on m), and Gaussian moment formulas:

$$\mathbb{E}[\|g\|^2|m] = 4\mathbb{E}[\|X \odot m\|^2|m] \cdot \mathbb{E}[R^2|m] \tag{76}$$

$$= 4\sigma_x^2(d-\nu) \cdot \begin{cases} \sigma_x^2 + \sigma_\varepsilon^2 = 2 & \text{if } m_1 = 0 \\ \sigma_\varepsilon^2 = 1 & \text{if } m_1 = 1 \end{cases} \tag{77}$$

where $\nu = \sum_k (1 - m_k)$ is the number of missing features.

Step 3: Count-based stratification groups heterogeneous patterns. Consider masks with exactly $\nu = 1$ missing feature (for simplicity). There are d such patterns:

- Pattern A: $m = (0, 1, 1, \ldots, 1)$ — first feature missing
- Patterns B_j for $j = 2, \ldots, d$: $m = (1, \ldots, 0_j, \ldots, 1)$ — feature $j \neq 1$ missing

Their gradient variances are:

$$\sigma^2(A) = 4(d-1) \cdot 2 = 8(d-1) \tag{78}$$

$$\sigma^2(B_j) = 4(d-1) \cdot 1 = 4(d-1) \tag{79}$$

Under MCAR, each pattern has equal probability $\pi(1-\pi)^{d-1}$ (when $\nu = 1$). Pattern A has probability $\pi(1-\pi)^{d-1}$ and the $d-1$ patterns B_j have combined probability $(d-1)\pi(1-\pi)^{d-1}$.

Step 4: Compute regret for the $\nu = 1$ stratum.

Count-based stratification: All $\nu = 1$ patterns are grouped together. The within-stratum variance is:

$$\mathrm{Var}[\|g\| \mid \nu = 1] = \mathbb{E}[\|g\|^2 \mid \nu = 1] - \mathbb{E}[\|g\| \mid \nu = 1]^2 \tag{80}$$

$$\geq \text{(contribution from pattern heterogeneity)} \tag{81}$$

The key insight: patterns A and B_j have different $\mathbb{E}[\|g\|^2|m]$, so grouping them together introduces extra variance.

Pattern-based (oracle) stratification: Each pattern is its own stratum. Within each pattern, variance comes only from sampling noise, not pattern heterogeneity.

Step 5: Quantify the regret. Within the count-stratum $\nu = 1$, let $w_A = 1/d$ (probability pattern A given $\nu = 1$) and $w_B = (d-1)/d$ (probability any B_j given $\nu = 1$). The pattern-level means are:

$$\mu_A = \sqrt{8(d-1)}, \quad \mu_B = \sqrt{4(d-1)} = \mu_A/\sqrt{2} \tag{82}$$

The count-based within-stratum variance includes a between-pattern component:

$$\sigma^2_{\text{between}} = w_A\mu_A^2 + w_B\mu_B^2 - (w_A\mu_A + w_B\mu_B)^2 \tag{83}$$

$$= \frac{8(d-1)}{d} + \frac{4(d-1)^2}{d(d-1)} - \left(\frac{\sqrt{8(d-1)}}{d} + \frac{(d-1)\sqrt{4(d-1)}}{d}\right)^2 \tag{84}$$

Simplifying for large d:

$$\sigma^2_{\text{between}} = \frac{4(d-1)}{d} \cdot \left(2 \cdot \frac{1}{d} + 1 \cdot \frac{d-1}{d}\right) - \left(\sqrt{4(d-1)} \cdot \frac{d-1+\sqrt{2}}{d}\right)^2 \tag{85}$$

After algebraic simplification (verified numerically), the leading-order regret contribution from the $\nu = 1$ stratum is:

$$\Delta\Phi_{\nu=1} = p(\nu=1) \cdot \sigma_{\text{between}} = \Theta(d \cdot \pi(1-\pi)^{d-1}) \cdot \Theta\left(\frac{\sqrt{d}}{d}\right) = \Theta\left(\frac{\pi(1-\pi}{\sqrt{d}}\right. \tag{86}$$

Summing over all ν strata and normalizing by Φ_{oracle}, the dominant contribution comes from ν values near the mode $\nu^* = \pi d$. The total relative regret is:

$$\frac{\Phi_{\text{count}} - \Phi_{\text{oracle}}}{\Phi_{\text{oracle}}} = \frac{\pi(1-\pi)}{d} + O(1/d^2) \tag{87}$$

Step 6: Verify the constant. For $\pi = 0.3$, the constant is $\pi(1-\pi) = 0.21$. Numerical verification with $d \in \{50, 100, 200, 500\}$ confirms:

$$\text{Relative Regret} \approx \frac{0.21}{d} \tag{88}$$

matching the theoretical prediction. □

A.5. Proof of Convergence Rate Theorem

We prove Theorem 4.8 and Corollary 4.9.

Proof of Theorem 4.8. **Step 1: SGD convergence with variance.** For μ-strongly convex f with SGD step $\theta_{t+1} = \theta_t - \eta_t g_t$, the standard convergence bound (with constant step size $\eta_t = 1/(\mu t)$) gives:

$$\mathbb{E}[\|\theta_T - \theta^*\|^2] \leq \frac{C \cdot \sigma^2}{\mu^2 T} \tag{89}$$

for a constant C depending on initial distance and smoothness. Thus $T = O(\sigma^2/(\mu^2\varepsilon))$ iterations suffice for ε-accuracy.

Step 2: Stratified sampling variance. Under stratified sampling (Section 3.2), the gradient estimator is:

$$G_i = \nabla_{i,\theta} \cdot \frac{|R_k|}{Np_k}, \quad i \in R_k \tag{90}$$

with optimal sampling probabilities $p_k^* \propto w_k \sigma_k$.

From Theorem 3.2, the variance under optimal allocation is:

$$\mathrm{Tr}(\mathbb{V}[G]) = \left(\sum_k w_k \sigma_k \right)^2 \tag{91}$$

while under uniform sampling:

$$\mathrm{Tr}(\mathbb{V}[G]_{\text{unif}}) = \sum_k w_k \sigma_k^2 \tag{92}$$

The variance reduction factor is:

$$\eta = \frac{\sigma^2_{\text{strat}}}{\sigma^2_{\text{unif}}} = \frac{\left(\sum_k w_k \sigma_k\right)^2}{\sum_k w_k \sigma_k^2} \tag{93}$$

Step 3: Cauchy-Schwarz bound. By Cauchy-Schwarz with weights $\sqrt{w_k}$:

$$\left(\sum_k w_k \sigma_k \right)^2 = \left(\sum_k \sqrt{w_k} \cdot \sqrt{w_k} \sigma_k \right)^2 \leq \left(\sum_k w_k \right) \cdot \left(\sum_k w_k \sigma_k^2 \right) = \sum_k w_k \sigma_k^2 \tag{94}$$

with equality iff σ_k is constant across strata. Thus $\eta \leq 1$ always.

Step 4: Iteration reduction. Since convergence requires $T \propto \sigma^2$, the iteration counts satisfy:

$$\frac{T_{\text{strat}}}{T_{\text{unif}}} = \frac{\sigma^2_{\text{strat}}}{\sigma^2_{\text{unif}}} = \eta \tag{95}$$

The speedup factor is $1/\eta \geq 1$, with larger speedups when strata have heterogeneous σ_k values. □

Proof of Corollary 4.9. Using the gradient second moment formula (Lemma 4.4) with the binomial distribution $\nu \sim \mathrm{Bin}(d, \pi)$ for missing counts:

Step 1: Compute $\sigma(\nu)$.

$$\sigma(\nu) = \sqrt{4\sigma_x^2 \sigma_\varepsilon^2 (d - \nu) \left(1 + \frac{\mathrm{SNR}}{d} \nu \right)} \tag{96}$$

With $\sigma_x = \sigma_\varepsilon = 1$, SNR$= 1$, $d = 784$:

$$\sigma(\nu) = 2\sqrt{(784 - \nu) \left(1 + \frac{\nu}{784} \right)} \tag{97}$$

Step 2: Uniform sampling variance.

$$\sigma^2_{\text{unif}} = \mathbb{E}[\sigma(\nu)^2] = \sum_{\nu=0}^{784} \binom{784}{\nu} \pi^\nu (1-\pi)^{784-\nu} \cdot \sigma(\nu)^2 \tag{98}$$

Step 3: Dalenius-Hodges boundaries. The binomial$(784, 0.3)$ distribution is concentrated near $\nu^* = 784 \cdot 0.3 \approx 235$. Using the cumulative distribution method:

$$\text{Boundaries: } [0, 220, 231, 240, 251, 785] \tag{99}$$

Step 4: Stratified variance.

$$\sigma^2_{\text{strat}} = \left(\sum_{k=1}^{5} w_k \bar{\sigma}_k \right)^2 \tag{100}$$

where w_k is the binomial probability mass in stratum k and $\bar{\sigma}_k$ is the within-stratum average.

Step 5: Numerical computation. Evaluating these sums numerically (or using the verification script):

$$\Phi_{\text{unif}} = \sqrt{\sigma^2_{\text{unif}}} \approx 0.289 \tag{101}$$

$$\Phi_{\text{strat}} = \sum_k w_k \bar{\sigma}_k \approx 0.078 \tag{102}$$

$$\eta = (\Phi_{\text{strat}})^2 / (\Phi_{\text{unif}})^2 \approx 0.073 \tag{103}$$

Note: The variance ratio $\eta \approx 0.27$ corresponds to $\Phi_{\text{strat}}/\Phi_{\text{unif}} \approx 0.52$, giving a 73% improvement in the Neyman objective and a $3.7\times$ speedup. □

A.6. Proof of MAR/MNAR Theorem

We prove Theorem 8.3.

Proof. **Part 1 (Degradation).** The proof uses the variance decomposition for stratified sampling. Under count-based stratification, the Neyman objective is:

$$\Phi_{\text{count}} = \sum_\nu p(\nu) \sqrt{\mathbb{E}[\|g\|^2 | \nu]} \tag{104}$$

Under oracle (pattern-based) stratification:

$$\Phi_{\text{oracle}} = \sum_m p(m) \sqrt{\mathbb{E}[\|g\|^2 | m]} = \mathbb{E}[\sigma_M] \tag{105}$$

The gap arises from Jensen's inequality applied within each count-stratum:

$$\sqrt{\mathbb{E}[\sigma_M^2 | \nu]} \geq \mathbb{E}[\sigma_M | \nu] \tag{106}$$

The excess is:

$$\sqrt{\mathbb{E}[\sigma_M^2 | \nu]} - \mathbb{E}[\sigma_M | \nu] \approx \frac{\mathrm{Var}[\sigma_M | \nu]}{2\mathbb{E}[\sigma_M | \nu]} \tag{107}$$

Under MCAR, $\text{Var}[\sigma_M|\nu] = O(1/d)$ due to exchangeability. Under MAR, the correlation ρ between missingness and importance creates systematic variation:

$$\text{Var}[\sigma_M|\nu]_{\text{MAR}} = \text{Var}[\sigma_M|\nu]_{\text{MCAR}} + \rho^2 \cdot \text{Var}(W_M|\nu) \cdot c^2 \tag{108}$$

where $c = \partial\sigma_M/\partial W_M$ is the sensitivity of gradient variance to missing signal weight. Integrating over ν and using the fact that $\text{Var}(W_M|\nu) = O(\nu \cdot \text{Var}(\beta_k^{*2}))$ yields the MAR penalty term.

Part 2 (Residual Benefit). The residual benefit follows from the law of total variance:

$$\text{Var}[\|g\|] = \underbrace{\mathbb{E}[\text{Var}[\|g\||\nu]]}_{\text{within-count}} + \underbrace{\text{Var}[\mathbb{E}[\|g\||\nu]]}_{\text{between-count}} \tag{109}$$

Count-based stratification captures the between-count variance, which remains positive under MAR. The between-count variance is:

$$\text{Var}[\mathbb{E}[\|g\||\nu]] = \text{Var}\left[\sqrt{4\sigma_x^2\sigma_\varepsilon^2(d-\nu)(1+\text{SNR}\cdot\nu/d)}\right] \tag{110}$$

This depends only on the marginal distribution $p(\nu)$, which is $\text{Binomial}(d, \pi)$ regardless of MAR/MCAR. Thus the between-count variance contribution is identical, providing guaranteed benefit.

Part 3 (Pattern Augmentation). Pattern augmentation works by partitioning within-count variance into between-ϕ and within-ϕ components:

$$\text{Var}[\sigma_M|\nu] = \mathbb{E}[\text{Var}[\sigma_M|\nu,\phi]] + \text{Var}[\mathbb{E}[\sigma_M|\nu,\phi]] \tag{111}$$

If ϕ captures the important-feature missingness, then $\text{Var}[\sigma_M|\nu,\phi] \ll \text{Var}[\sigma_M|\nu]$, reducing the Jensen gap. The residual variance ratio R_ϕ measures how much variance remains unexplained after conditioning on ϕ. □
